# AN EVALUATION OF THE PERFORMANCE OF A NEW STORM TRACKING METHODOLOGY

## 1. Introduction

Weather forecasts made by the Fleet Numerical Oceanography Center (FNOC) are based on a numerical weather prediction model called the Naval Operational Global Atmospheric Prediction System (NOGAPS). Until 1983 the only available measures of model performance were of a global nature (aggregated over all the weather systems monitored), such as means, variances and root mean square errors. The operational field forecasters, on the other hand, prefer error statistics relevant at the synoptic level, i.e., measures pertaining to forecasts of individual storms and troughs. Such measures would enable these forecasters to provide better subjective forecasts at the regional level. In 1982, the Naval Environmental Prediction Research Facility (NEPRF) began the development of the Systematic Error Identification System (SEIS); the primary data reduction methodology within SEIS is the Vortex Tracking Program (VTP). In the VTP, an atmospheric low/high pressure system is mathematically represented as a generalized six parameter elliptic function. The six parameters correspond with the primary features of a storm, viz., the amplitude  $A$ ,  $R$  the semi-major of the elliptic representation of the storm,  $e$  the eccentricity or the ratio of the semi-major to the semi-minor,  $\alpha$  the orientation of the ellipse and  $X_0$ ,  $Y_0$  the coordinates of the center of the storm. The units of measurement are millibars (mb) for  $A$ , and degrees with respect to the North for  $\alpha$  while  $R$ ,  $X_0$ ,  $Y_0$  are measured in terms of a  $63 \times 63$  FNOC hemispheric grid units. For each valid storm, the VTP uses an iterated non-linear least squares scheme to estimate  $A$ ,  $R$ ,  $e$ ,  $\alpha$ ,  $X_0$ ,  $Y_0$  within the sea level pressure field for the analysis at time  $t$  as well as for the associated 12, 24, 36, 48 and 60 hour forecasts produced by NOGAPS. The iteration scheme requires a set of initial guess values for the parameters to produce the estimates for the analysis field at time  $t$ . These estimates are in turn used as guess values to produce the 12 hour forecasts; the 12 hour parameter

forecasts are used to generate the 24 hour forecasts and so on. The estimated parameter values for the analysis field at time  $t$  are also used as the first guesses for the analysis field at  $t + 12$  hours. The estimates for the analysis field are usually referred to as verification values. Corresponding to each set of forecasted parameter values there will be a verification set obtained using the current (for the forecasted time) sea level pressure data. The difference between a forecasted value and its verification value is called the forecast error. SEIS, thus, provides the capability to track individual weather systems (by tracking the movement of the elliptic representation) and also a means to measure and analyze the tracking errors.

The modified NOGAPS model has been running on a real time basis since mid 1983. During the life cycle of each valid storm, twice each day (at noon and at midnight GMT), the elliptic parameter estimates are produced for the analysis field and the associated 12, 24, 36, 48 and 60 hour forecast fields. References [1], [2] and [3] discuss the VTP and SEIS models in more detail.

The objective of this project is the exploratory statistical analysis of the forecast errors to assess the performance of the SEIS/VTP model. Data on 80 storms, covering the North Pacific Ocean Basin, observed during the period January-May 1984 has been used in this study. The results of the analysis are described in the following sections. Section 2 contains overall measures of performance of SEIS/VTP, primarily summary statistics of forecast errors pooled over all the 80 storms. Error statistics pertaining to the tracking of individual storms are presented in Section 3. Conclusions and topics for further research are discussed in Section 4.

## 2. Analysis of Forecast Errors

A forecast error is defined as the difference between a forecasted parameter value and its verification value; an absolute forecast error is the absolute value of a forecast error. For each of the five forecasting periods (12, 24, 36, 48 and 60 hours) the forecast and the absolute forecast errors were subjected to various statistical analyses. Tables 1 and 2 contain the means ( $\bar{X}$ ) and standard deviations (S) for these errors.

TABLE 1

TABLE 2

SUMMARY STATISTICS OF ABSOLUTE FORECAST ERRORS

Forecast Period	Number of Samples	A		$\epsilon$		R		$\alpha$		$X_0$		$Y_0$	
		$\bar{x}$	s	$\bar{x}$	s	$\bar{x}$	s	$\bar{x}$	s	$\bar{x}$	s	$\bar{x}$	s
12	487	3.37	3.79	0.35	1.23	0.85	0.98	28.79	40.93	0.50	0.59	0.55	0.
24	429	5.56	4.57	0.92	1.15	1.00	0.98	32.65	40.89	0.69	0.73	0.78	0.
36	371	6.34	5.39	1.07	1.52	1.19	1.28	37.26	42.18	0.87	0.86	1.02	1.
48	329	7.63	6.32	1.07	1.51	1.19	1.32	36.65	39.92	0.97	0.93	1.23	1.
60	288	8.33	6.92	1.20	1.67	1.20	1.42	35.20	36.99	1.04	1.01	1.36	1.

The following general conclusions appear warranted. The NOGAPS forecasting methodology does forecast the parameters  $A$ ,  $R$ ,  $\varepsilon$ ,  $X_0$ ,  $Y_0$  quite well. With regards to the forecasting of the orientation  $\alpha$ , although the mean errors are not excessive, the standard deviations are somewhat high. In many cases the forecast errors are negative indicating a negative bias, i.e., the forecasted values tend to be on the low side of the verification values. With a few exceptions, the means and standard deviations increase with an increase in the forecasting period; this is to be expected in view of the higher levels of uncertainty involved.

The autocorrelations for lags 1 to 5 between the forecast errors are presented in Table 3. Except for the lag-one autocorrelations of about .30 for the forecast errors of  $A$ ,  $X_0$ ,  $Y_0$  the rest of the autocorrelations are quite negligible. This implies that a large error in forecasting a parameter at a given time will not have a lasting effect on future forecast errors. Also, the correlation matrices (correlations between the errors in forecasting  $A$ ,  $\alpha$ ,  $R$ ,  $\epsilon$ ,  $X_0$ ,  $Y_0$ ) in Table 4 show that these correlations are negligible with one exception -- the correlation between the errors in forecasting  $R$  and  $\epsilon$  is around .5. This may be interpreted to mean (with the one exception) that a large forecast error for one parameter will not have a detrimental effect on the estimates of the other parameters.

In an attempt to model the statistical behavior, gamma distribution were fit to the 12, 24, 36 and 48 hour absolute forecast errors. The histograms with the fitted gamma distribution superimposed are in Figures 1-18. Gamma distributions appear to serve as good statistical models of the absolute forecast errors for  $A$  and  $R$ . In the other cases, the lack of fit may be attributed to a higher peakedness in the data; a Weibull distribution may provide a better fit. Although no graphs are presented, gamma distributions did not provide a good fit to the forecast errors (appropriately translated/shifted to make them positive) also. Further work will be necessary to determine the most appropriate statistical distributions to model the probabilistic behavior of the forecast errors. Proper statistical modeling of the error data could be useful for exploring the development of uncertainty contours (confidence regions) for the movements of weather systems.

### 3. Statistics of Individual Weather Systems

To evaluate the performances of SEIS, in tracking individual weather systems, and the NOGAPS model in forecasting weather systems, data on 20 storms with at least 10 records per storm (i.e., 10 sets of forecasted and verification values per storm) were examined. The means ( $\bar{X}$ ) and standard deviations (S) of the forecast errors for these 20 storms are in Table 5.

The trends in the forecast errors are similar to the global trends observed in the previous section; with the exception of the forecasting of  $\alpha$ , the forecast errors are very small even at the individual storm level. The iterated non-linear least square procedure in VTP requires initial guess values for each of the parameters  $A$ ,  $\epsilon$ ,  $R$ ,  $\alpha$ ,  $X_0$ ,  $Y_0$ ; the initial guess for  $\alpha$  is always specified as zero. We conjecture that this may be the cause of the somewhat erratic forecasts of  $\alpha$ . A better initial guess, closer to the true value, may result in a better forecast of  $\alpha$ . The SEIS/VTP appears to be exceptionally good in forecasting the center of a storm.

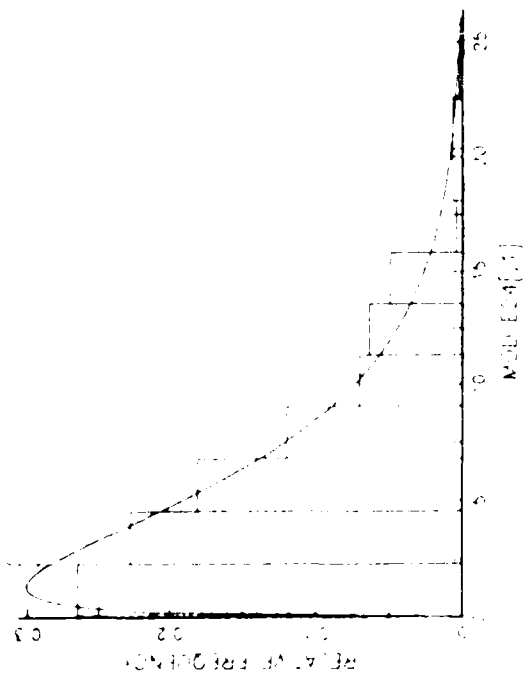

For each of the 20 storms the forecasted values of  $A$ ,  $X_0$  and  $Y_0$  were plotted against their respective verification values. In several cases, the scatter plots indicated an approximate linear relationship between the forecasted and verification values. A few of these scatter plots are shown in Figures 19-30. A linear regression analysis was, therefore, performed with the forecasted value as the independent variable and the verification value as the dependent variable. The least squares estimates of the intercept and slope of the fitted line and also the estimated coefficient of correlation (a measure of goodness of the fitted line) are in Table 6.

The overall conclusion is that the incorporation of the SEIS and VTP methodology within the NOGAPS model has improved the storm tracking capability of NOGAPS and the elliptic representation of storms provides a good means of providing synoptic level error statistics to the field forecasters.

We propose the following topics for further study and research:

1. Determine the most appropriate probability distributions to describe the probabilistic behavior of the forecast errors. The indications are that the Weibull family may provide a good fit to the absolute error data.
2. Develop procedures to generate uncertainty contours/ confidence regions around the forecasted elliptic representations of a storm based on the probability distributions of the forecast errors.
3. Examine more data to determine the functional relationship (if it exists) between the forecasted and verification values of the elliptic parameters. Different stratification schemes for the storm data such as by geographic regions and by climatic seasons could lead to the identification of sources of systematic errors and the means of remediation.

#### 4. Conclusions and Recommendations

This study has demonstrated that the NOGAPS model performs exceedingly well in forecasting five of the six parameters of the elliptic representation of a storm. The maximum mean absolute error in forecasting the amplitude  $A$  is 8.38 (Table 2) which is less than 1% of the verification values that range between 900 and 1,000; the maximum standard deviation of these errors is 6.92. Similar positive statements apply to the errors in forecasting  $\epsilon$ ,  $R$ ,  $X_0$ ,  $Y_0$  as can be seen from Tables 1 and 2 and the single high mode close to zero in the histograms (Figures 1-18) of absolute errors.

The autocorrelations (Table 3) between the errors in successive forecasts of any of the six parameters indicate that these errors may, for all practical purposes, be treated as independent. Similarly, for each forecast period, the errors in forecasting the parameters  $A$ ,  $\epsilon$ ,  $R$ ,  $\alpha$ ,  $X_0$ ,  $Y_0$  appear to be independent (Table 4). What this implies is that a large error in forecasting a parameter may not have a lasting effect on other forecasts nor will it have a carry over effect on forecasting the other parameters.

Even at the individual storm level, the mean forecast errors and their standard deviations are quite small; once again the exception is the parameter  $\alpha$ . Scatter plots of the forecasted values versus the verification values indicated a linear relationship between the two sets, in several cases. Regression analyses to fit straight lines to the data confirmed this observation (Table 6 and Figures 19-30). When the data was stratified according to the forecasts period, e.g., all 12 hour forecasts are treated as one group, and a separate regression analysis performed for each group the linear relationship was accentuated (Table 7).

TABLE 7

that can be made from the correlations in Table 7 is that the 12 and 24 hour forecasts, and to a lesser extent the 36 hour forecasts correspond well with the verification values; the efficiency of the forecasting scheme appears to drop after the 36 hour forecasts.

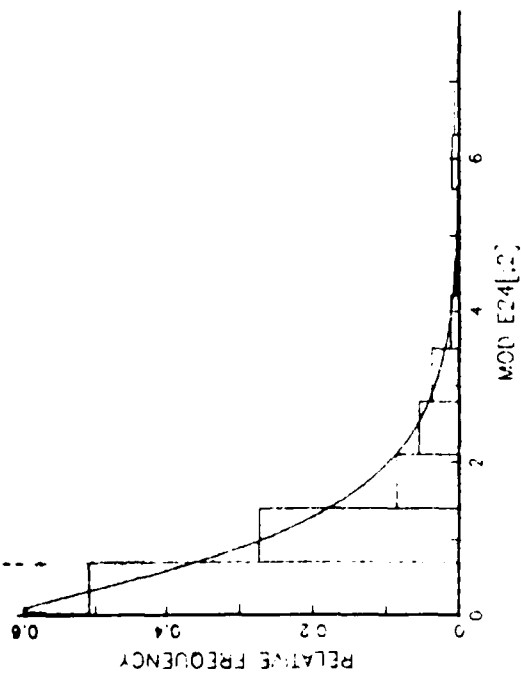

The regression analyses confirmed what was observed from the scatter plots, namely, a linear fit in many cases. If the functional relationship between the forecasted and verification values can be determined with good precision, corrective action can be taken to remove this source of systematic error in the forecasting scheme. However, the results in Table 6 do not lend themselves to the determination of the functional relationship. More data needs to be examined and different ways of stratifying the data such as by geographic regions and/or climatic seasons may prove to be profitable. Another possibility is to group the available records for a storm according to the forecast periods, i.e., all 12 hour forecasts as one group, all 24 hour forecasts as another group, etc. Of course, this scheme can only be applied to storms with large numbers of records. We tried this approach on 4 out of the 20 storms (storms 5, 13, 18 and 19, each with 60 or more records). The records for each storm were formed into five groups, one for each of the forecast periods and a separate regression analysis was performed for each group.

The estimated regression parameters in Table 7 reveal a much stronger linear relationship when the data is stratified according to the forecast period. Also, one can discern a definite pattern in the relationship between the forecasted and verification values of the storm's amplitude  $A$ . For the 12 hour forecasts, the relationship is linear with an intercept value of about 260 and slope .7; the intercept and slope values for the 48 hour forecasts are around 475 and .5 respectively. This is only an empirical observation and a more extensive study will be necessary to confirm this. Even though there is a strong correlation between the forecasted and verification values of  $X_0$  and  $Y_0$ , no pattern is evident in the estimates of the intercepts and slopes of the fitted lines. Another observation

SCATTER PLOT, SSZ=19

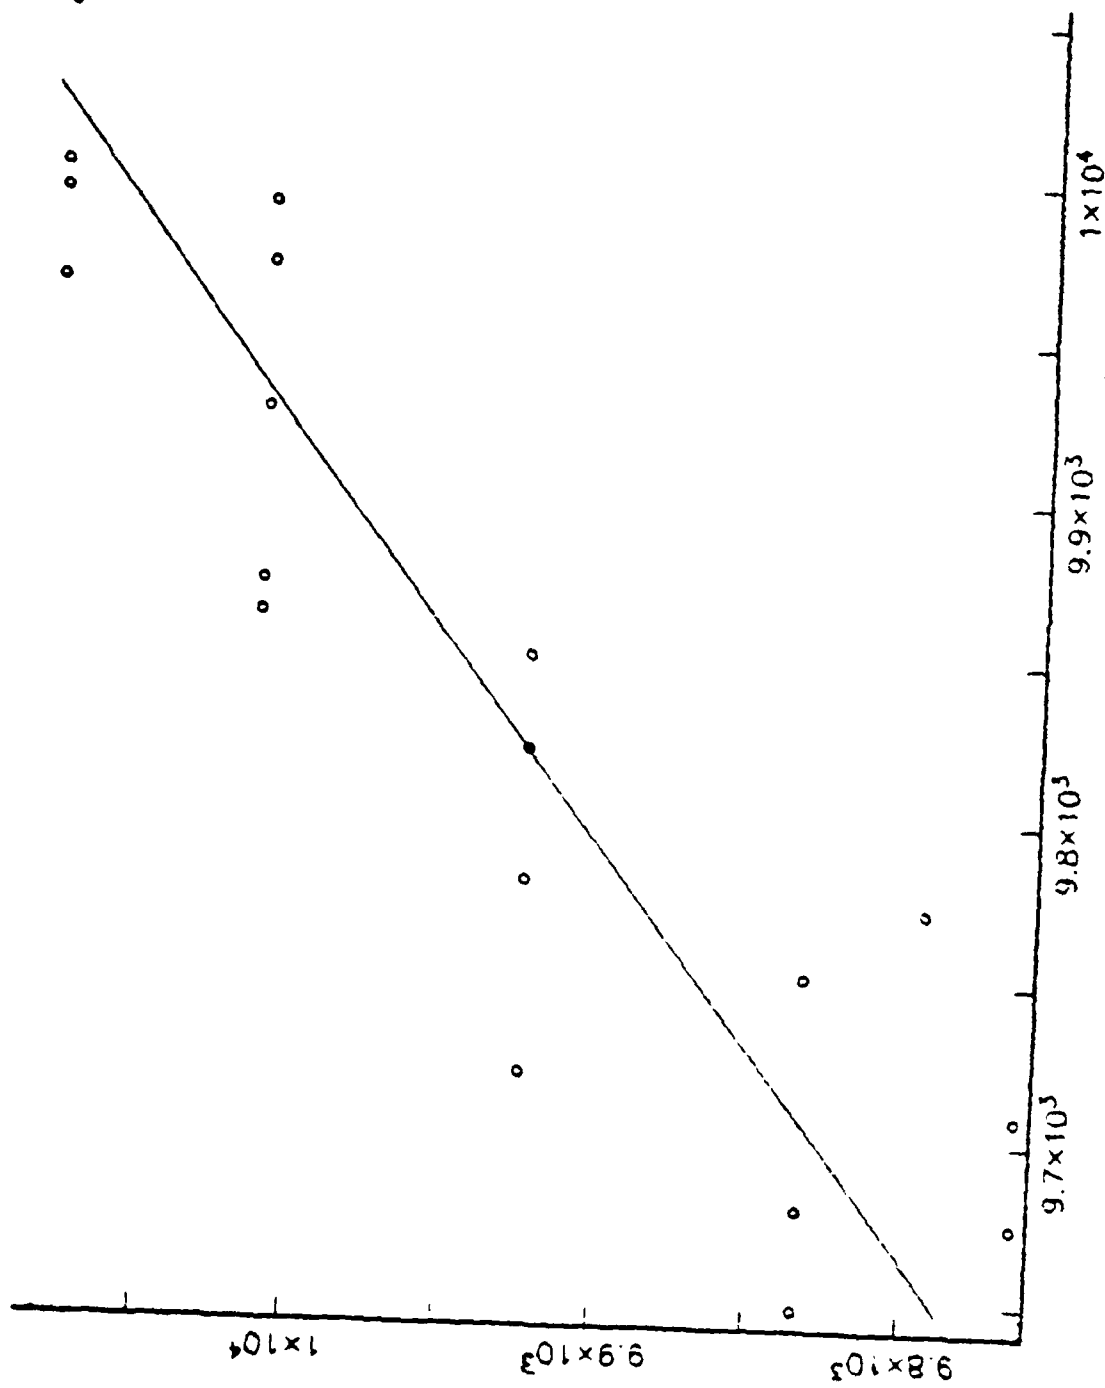

FIGURE 19  
FORECASTED VALUES OF AMPLITUDE - STORM 2

Scatter plot showing the relationship between the Value (X-axis) and the Verification Value (Y-axis) for 1000 samples. The X-axis ranges from  $9.85 \times 10^3$  to  $1.005 \times 10^4$ . The Y-axis ranges from 9900 to 9980. A linear regression line is fitted to the data points, indicating a strong positive correlation.
